DIELECTRIC ABSORPTION IN METHYL AND ETHYL ESTERS
OF LONG-CHAIN ACIDS

By N. E. ROBINSON* and H. K. WELSH*

[Manuscript received February 28, 1969]

Methyl esters of aliphatic acids have occupied an important position in the study of dielectric absorption in long-chain molecular crystals. They were the first to be studied over a wide frequency range over a range of temperatures. These studies showed that methyl esters have two absorptions, one at microwave frequencies, the other in the radio frequency range. The former, which does not depend on the chain-length of the molecule and which is absent in compounds having the dipole close to the middle of the chain, appears to be due to motion of the end dipole of the molecule. It will not be considered further in the present communication.

The lower frequency absorption is strongly dependent on the chain-length of the molecule. Similar dependence on chain-length is found for the corresponding absorption in ethyl esters. It is believed that the absorption is due to rotation of the whole molecule, occurring near an imperfection of the crystal lattice.

At present the crystal structures of only these two series of aliphatic esters (methyl esters and ethyl esters) are known in any detail, so that the two series are critical to discussion of mechanism. They have essentially the same side-by-side packing of chains, but differ in end packing.

Unfortunately the activation energies for these series reported from this Laboratory are of low accuracy, illustrated by the discrepancy between our value for methyl stearate (11 kcal/mole) and a value (12.7 kcal/mole) determined recently by Broadhurst. The inaccuracy is due mainly to the use of a limited temperature range for the measurements.

It appeared desirable to remeasure these activation energies before attempting deductions from the way in which they vary with chain-length. We have therefore

remeasured the esters previously reported from room temperatures down to \(-70^\circ C\) and have taken the opportunity to extend the range of chain-lengths. Good linear Arrhenius plots were obtained from which the activation energy, \(\Delta E\), and logarithm of the frequency factor, \(\log A\), were determined. These are listed in Table 1, together with the chain-length, \(n\), and the energy gap, \(\Delta E_0\), which was determined from the temperature variation of the intensity.

When plotted as a function of chain-length (Fig. 1) both series lie on the same line, with slope 0.5 kcal/mole/chain atom. Such a relationship had also been suggested by the earlier results\(^{10}\) but with a distinctly different slope (1.3). The identity of slope for the two series is compatible with the general similarity of chain packing. The fact that both series lie on the same line suggests that end packing has little effect on barrier height.

An attempt\textsuperscript{11} has been made to identify the temperature for maximum mechanical absorption at 1 Hz in a number of normal paraffins with that for dielectric absorption at the same frequency, calculated from the data which have now been corrected. It is remarkable that the revision of the dielectric parameters has little effect on the trend of the calculated temperatures. This insensitivity to major changes in parameters tends to confirm the suggestion\textsuperscript{12} that the difference between chain-length dependence of the two sets of temperatures is significant, indicating that different processes are involved.
