**Abstract.** During spring and summer of 2007, 76 fungal isolates were recovered from different *Prunus* species in West Azerbaijan and Tehran provinces of Iran. Based on morphological characteristics, all isolates were identified as *Wilsonomyces carpophilus*. The occurrence of shot hole disease symptoms on almond, plum, peach and nectarine fruits, apricot twigs in orchards was observed. The first pathogenicity tests with *W. carpophilus* in Iran, using seven *Prunus* species, are reported.

Shot hole disease of stone fruit trees, caused by *Wilsonomyces carpophilus* (Lév.) Adaskaveg, Ogawa & Butler (= *Stigmina carpophila* (Lév.) M. B. Ellis and *Coryneum beijerinckii* Oud.) (Adaskaveg *et al.* 1990) is a serious disease of *Prunus* species in many parts of the temperate to semiarid regions of the world (Ogawa *et al.* 1995) as well as Iran (Ashkan and Asadi 1971). This disease is called shot hole because of the symptoms caused by fungus on the leaves of host trees. The disease was first reported from the northern region in Iran by Esfandiari (1947). The disease exists in most fruit-growing areas of Iran and is particularly destructive on apricot (*Prunus armeniaca* L.) in Azerbaijan province (Ashkan and Asadi 1971). Ashkan and Asadi (1971) isolated the fungus only from infected apricot fruits and observed symptoms similar to the shot hole disease on apricot, sweet cherry (*Prunus avium* L.) and sour cherry (*Prunus cerasus* L.) fruits, on almond (*Prunus dulcis* (Mill.) D. A. Webb.), peach (*Prunus persica* (L.) Batsch.), sweet cherry and sour cherry twigs and on leaves of different *Prunus* species. However, there have been no reports of the isolation of the causal agent of shot hole disease from other *Prunus* species in Iran, or pathogenicity tests.

During spring and summer of 2007, 76 monoconidial isolates were recovered from infected leaves, fruits and twigs of different *Prunus* species (apricot, almond, peach, nectarine (*Prunus persica* var. *nectarina*), plum (*Prunus domestica* L.), sweet cherry and sour cherry) in West Azerbaijan and Tehran provinces of Iran. All isolates were identified as *Wilsonomyces carpophilus* based on morphological and physiological characters and optimal temperatures for growth in culture (Adaskaveg *et al.* 1990). Hyphae were septate, thin-walled, branched, 2.5–7.5 μm in diameter, sub-hyaline to light brown. Conidiophores in the sporodochia were sympodial (Fig. 1), scars on conidiophores inconspicuous to conspicuous, conidia fusoid with apical cell ovate and basal cell truncate, 2.5–5 μm at the base, 2–4 transverse septa (occasionally 0–8 septa) (Fig. 2), holoblastic, rhexolytic, 20–67.5 × 7.5–15 μm, sub-hyaline to golden brown, dark olivaceous to black in mass. No growth was observed in culture below 5°C or above 30°C.

Twigs lesions mostly 3–10 mm in diameter were observed on peach (Fig. 3), almond and apricot. Leaf and fruit lesions began as small purplish areas that expanded to brownish spots 3–10 mm in diameter. On fruits, lesions developed mostly on the upper side and eventually became corky and rough. Lesions were observed on the fruit of plum (Fig. 4), almond, apricot, peach and nectarine. Leaf lesions abscise in a warm and dry environment. Leaf symptoms were observed on different *Prunus* species (apricot, almond, peach, nectarine, plum, sweet cherry and sour cherry). The fungus infected and killed dormant buds. Dead buds were...
occasionally covered with a gummy exudate that gave them a varnished appearance. Infection of buds was observed on almond and peach (Fig. 3).

Stone fruit seedlings (apricot, almond, peach, nectarine, plum, sweet cherry and sour cherry) were used for pathogenecity tests in the greenhouse. Ten leaves and twigs from three seedlings of each Prunus species were sprayed with a conidial suspension (10^5 conidia/mL). Isolates used were KHG2, URH9 and KHJ1 collected from sweet cherry leaves (Khoy, West Azerbaijan), peach (Urmia, West Azerbaijan) and plum (Khoy, West Azerbaijan) fruits respectively. Inoculated seedlings were maintained at 20 ± 2°C and greater than 75% relative humidity (Grove 2002). Control plants were sprayed only with distilled water. Shot hole symptoms were reproduced on all inoculated plants. The symptoms were similar to those observed in the orchards and the fungus was recovered from all infected parts. Symptoms were not observed on control plants. This is the first report of successful pathogenicity tests with W. carpophilus in Iran. Ashkan and Asadi (1971) observed symptoms similar to the shot hole disease on leaves of apple (Malus domestica Borkh.) and pear (Pyrus communis L.) grown among the highly infected apricot trees in orchards, but they could not isolate the pathogen. We observed no symptoms of shot hole disease on apple and pear trees in orchards in our studies.
