**Abstract: Aim:** In the absence of published state-wide notification data, the aim of this study was to analyse trends in notifiable blood lead levels (hereafter referred to as lead poisoning) in NSW from 1998 to 2008, to help inform lead poisoning notification policy. **Methods:** NSW blood lead poisoning notification data for 1998–2008 were extracted from the Notifiable Diseases Database and analysed by age, gender and Area Health Service of residence. **Results:** There were 6000 lead poisoning notifications from 1998 to 2008, with an average annual notification rate of 11.8 per 100 000 population for 1998–2003. This rate declined to an average of 4.0 per 100 000 population in the period 2004–2008. Males accounted for 92% of notifications, and males aged 20–59 years had average notification rates between 20 and 27 per 100 000 population. Children aged 0–4 years had notification rates of 9.3 per 100 000 population in girls and 13.6 per 100 000 population in boys. **Conclusion:** Notification rates have fallen dramatically, however children aged 0–4 years and men are disproportionately represented in lead poisoning notifications.

Lead is a naturally occurring mineral found within the Earth's crust in many parts of the world.<sup>1</sup> Lead poisoning occurring after exposure to lead has been of public health importance worldwide for centuries.<sup>2</sup> In 2009 the Australian National Health and Medical Research Council made a public statement that there is no safe level of lead exposure,

and recommended that all Australians have blood lead levels less than 10 µg/dL.<sup>3</sup>

The routes of lead exposure include ingestion, inhalation and skin contact. Once lead is absorbed into the bloodstream it spreads throughout the body, where it can affect the nervous, haematopoietic, endocrine, renal, skeletal and reproductive systems.<sup>1,4</sup> The potential health outcomes from lead poisoning vary between individuals and are due to the route of exposure, the dose absorbed, the duration of exposure and the person's age.<sup>1,3,4</sup> Children and pregnant women are considered the most sensitive to lead exposure; children absorb 40–70% of ingested lead compared to 10–20% in adults,<sup>5</sup> while women exposed before or during pregnancy transfer lead to the foetus via the placenta, and after pregnancy to the infant in breastmilk.<sup>3</sup>

Acute lead poisoning occurs at blood lead levels of 70 µg/dL or higher, and is considered a clinical emergency.<sup>3</sup> At these levels, signs and symptoms range from stomach pain and vomiting to encephalopathy and death. The long-term consequences of exposures in children include reduction in intellectual development even when blood lead levels are less than 10 µg/dL.<sup>6</sup> Treatment for lead poisoning is limited to the use of chelating agents that bind to lead in the blood and assist excretion in urine. Chelating agents can be used in adults with levels above 50 µg/dL,<sup>7</sup> whereas chelation in children with levels less than 45 µg/dL does not improve long-term behavioural or cognitive outcomes.<sup>8</sup> There is also concern that chelation therapy will redistribute lead to susceptible organs, including the brain, where it may be reabsorbed.<sup>9</sup>

Lead mining and smelter activities that cause lead-rich emissions to be blown into residential areas and deposited as dust in and around houses and gardens are the most common sources of contamination of human environments.<sup>1</sup> In the past lead was used in applications including face powders, and for preserving wine,<sup>2</sup> while more recently lead and lead alloys have been used in everyday products such as paint, car batteries and plastic coatings.<sup>3</sup> In Australia, lead was added to petrol to improve engine combustion performance from the 1930s until 2002, despite public health concerns about lead exposure.<sup>10</sup> The use of leaded petrol resulted in widespread contamination of dust and soil in urban and industrial areas, causing increased blood lead levels in people exposed, particularly children.<sup>11</sup> Improved awareness about the

effects of lead and the introduction of legislation in Australia has resulted in the reduction and removal of lead from car fuels and paints.<sup>12,13</sup>

In New South Wales (NSW) active screening for lead poisoning has been conducted for children and for workers exposed to lead since the early 1990s. In December 2011, the mandatory notification of blood lead concentrations 15 µg/dL or above was changed, under the *NSW Public Health Act 1991\**, to the lower level of 10 µg/dL or above.<sup>14</sup>

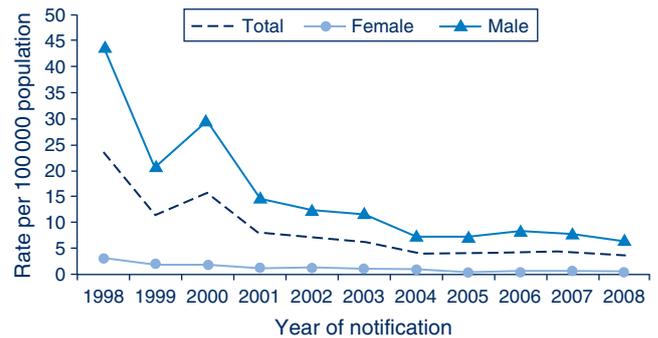

The aim of this study was to describe trends in notifications of lead poisoning in NSW from 1998 to 2008 to help inform public health policy.

## Methods

In NSW the notification of lead poisoning is mandatory for hospitals, clinicians and laboratories. Notifications are based on the results of a confirmatory venous blood sample to determine the lead concentration, which is measured in micrograms per decilitre (µg/dL). Between 1998 and 2008, a blood lead concentration of 15 µg/dL or more was classified as lead poisoning and was notifiable to the then NSW Department of Health.<sup>15</sup> Notified cases were then investigated by local public health units.<sup>16</sup> The investigating public health unit staff entered demographic information and blood lead levels of the cases into the Notifiable Diseases Database (NDD), which was used for the collection of notifiable disease case information in NSW until the implementation of the Notifiable Conditions Information Management System in 2010. Data from active surveillance programs conducted in occupational settings and child blood lead screening programs were included in routine NDD data. Active surveillance programs included blood lead screening in children in the north Lake Macquarie area from 1993 to 2006, and continuous surveillance in children in Broken Hill since 1991.

All notifications of lead poisoning in NSW for the period 1998–2008 were extracted from the NDD using the Health Outcomes Information Statistical Toolkit (HOIST). The data were analysed using SAS<sup>®</sup> (version 9.1.3, SAS Institute, Cary, NC, USA) and Microsoft Excel. Population estimates were obtained from the Australian Bureau of Statistics. Due to changes in Area Health Service boundaries, area of residence was defined by the NSW Health pre-2005 (former) Area Health Services ( $n = 17$ ).

As a major source of lead notifications ceased operation in 2003, analysis by time period was divided into time period 1 (1998–2003) and time period 2 (2004–2008). Data were analysed by gender, age group, (former) Area Health Service, blood lead concentration and occupation. Occupational variables were identified from a predetermined

**Figure 1.** Annual lead poisoning notification rates per 100 000 population, for males and females, NSW, 1998–2008.

list in the NDD; some of these served as a proxy for sources of lead exposure (e.g. lead smelter worker or miner).

## Results

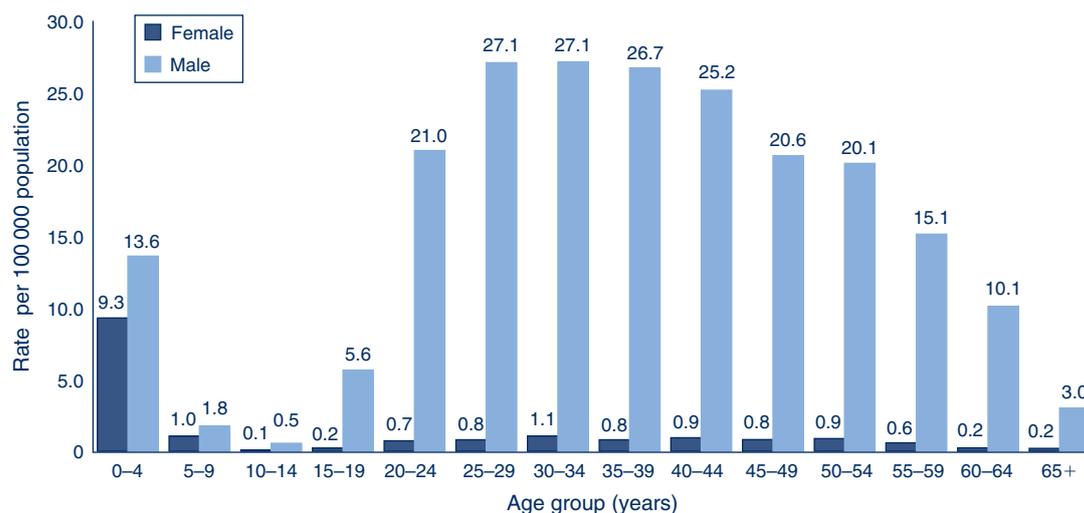

There were 6000 lead poisoning notifications in NSW for the period 1998–2008, with an average annual notification rate of 8.2 per 100 000 population. The highest annual notification rate was in 1998 (23.0 per 100 000 population,  $n = 1400$ ). Notification rates declined each year, with the exception of 2000 (Figure 1).

### Gender and age

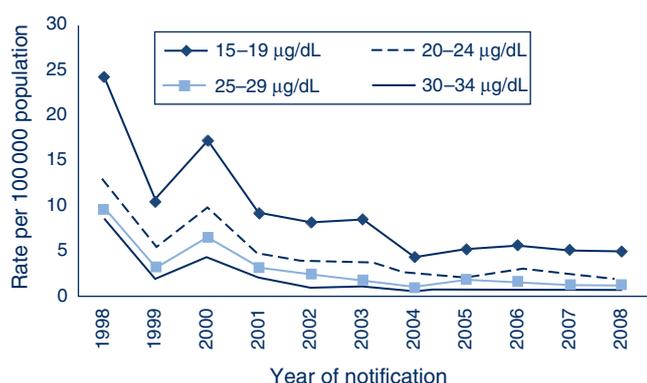

Males accounted for 92% ( $n = 5538$ ) of all notifications with a notification rate of 15.2 per 100 000 population for the period 1998–2008. The highest notification rate for males was 43.0 per 100 000 population in 1998; by 2004, annual notification rates in males had decreased to below 10.0 per 100 000 population (Figure 1). For females, the notification rate began at below 5.0 per 100 000 population in 1998 and steadily declined to below 1.0 per 100 000 population in 2008 (Figure 1).

People notified with lead poisoning between 1998 and 2008 ranged in age from 0 to 87 years. Men aged 25–34 had the highest notification rate of 27.1 per 100 000 population, while the lowest notification rates were in 10–14-year old boys and girls. The gender differences become more noticeable at 15 years of age (Figure 2). Seventy-eight percent of notifications ( $n = 4701$ ) were observed in men aged 20–59 years, who had an annual notification rate of almost 70.0 per 100 000 population in 1998, which declined to 10.0 per 100 000 population in 2004.

The 0–4-year age group accounted for 9.3% of notifications ( $n = 559$ ), of which 60% were in boys. The notification rate in girls aged 0–4 years was 9.3 per 100 000 population, and for the same age group of boys, 13.6 per 100 000 population (Figure 2). The highest annual

**Figure 3. Annual lead poisoning notification rates per 100 000 population for four blood lead concentrations, in men aged 20-59 years, NSW, 1998-2008.**  
 Source: Notifiable Diseases Database (since 2010, the Notifiable Conditions Information Management System), NSW Ministry of Health.

notification rate for boys aged 0-4 years was 30.0 per 100 000 population in 1999.

### Blood lead concentrations

Blood lead concentrations were recorded for 96.6% ( $n = 5795$ ) of notifications. Forty-three percent ( $n = 2503$ ) of blood lead concentrations were in the lowest notifiable range (15-19 µg/dL), while 54% ( $n = 3011$ ) were in the 20-49 µg/dL range, 2% ( $n = 125$ ) were in the 50-69 µg/dL range, and 1% ( $n = 56$ ) were 70 µg/dL or above. Figure 3 shows a further breakdown of notification rates by year, stratified by blood lead concentrations, in men aged 20-59 years, and demonstrates the downward trend in notification rates of blood lead concentrations in all years except 2000.

### Geographic distribution of notifications

Sixty-two percent ( $n = 3732$ ) of lead poisoning notifications were in locations outside of Sydney. The highest notification rates in 1998-2003 were 227.4 per 100 000 population in the former Far West Area Health Service, and 52.1 per 100 000 population in the former Hunter Area Health Service (Table 1). Over the period of analysis, lead poisoning notifications declined by 50% or greater in most Area Health Services: the former Macquarie Area Health Service increased by 230%, and the former Mid West Area Health Service increased by 39% (Table 1). From 1998 to 2008, 68.9% of lead poisoning notifications in children aged 0-4 years were in the former Far West Area Health Service which had a notification rate of 104.5 per 10 000 population. The former Hunter Area Health Service accounted for 14% (1.9 per 10 000 population), while 12.3% of notifications in the 0-4-year age group were from Sydney (0.24 per 10 000 population).

### Occupation

Occupational information was recorded for 37% of all adult notifications. Women had occupation recorded in 10% ( $n = 29$ ) of cases, while 40% of men had occupation recorded. Occupations with the highest proportions of notifications were lead smelter employees (37%;  $n = 735$ ) and miners (23%;  $n = 453$ ). For the period 1998-2002 (with the exception of 1999), smelter workers had the highest frequency of notifications, after which (with the exception of 2005) miners had the highest number of notifications (Figure 4). Other occupational categories identified with high notification rates included contractors (13%) and factory workers (10%).

Table 1. Average annual lead poisoning notifications and rates per 100 000 population, in NSW, by former Area Health Service (AHS), categorised by two time periods (TP1: 1998–2003 and TP2: 2004–2008) and the percentage reduction in notifications between time periods

## Discussion

There was a 70% reduction in lead poisoning notifications in NSW from 1998 to 2008, with fewer than 250 notifications each year since 2004. Men of working age and children aged 0–4 years are disproportionately represented

in lead poisoning notifications, with rates among men more than three times higher than among women. Populations in the former Far West, Hunter and Macquarie Area Health Services of NSW had the highest notification rates for lead poisoning.

The interpretation of this study is limited by data quality, with more than half of adult cases missing occupational data. Because the source of lead exposure was not available, occupation was used as a proxy for the source of exposure. In future, a review of case files from lead poisoning investigations and the recent inclusion of a variable for exposure site in the new notification data management system will help describe sources, without the need to use proxies. There is also likely to be a selection bias due to active surveillance programs, and greater awareness of public health practitioners in geographical areas, age groups and occupations at high risk. Screening has been important for understanding the epidemiology of lead exposure, because the acute symptoms of lead poisoning are not present at lower blood lead concentrations.<sup>1,3</sup> However, the likely selection bias for children and men means that women will tend to be under-represented in notification data. The reporting of more robust

information about testing, including the reason for testing (i.e. occupational vs. childhood screening or clinical suspicion) would help clarify the extent of this selection bias.

Notification rates of lead poisoning in NSW have been linked to occupational activities. For more than 100 years, mining and, formerly, smelting, have occurred in Broken Hill (former Far West Area Health Service),<sup>17</sup> and smelting has occurred in the north Lake Macquarie area (former Hunter Area Health Service).<sup>18</sup> There are marked differences in the ages of notified cases in these two locations. In the former Hunter Area Health Service, 90% of cases were in adults aged 20–59 years, whilst in the former Far West Area Health Service, children aged 0–4 years accounted for 52% ( $n = 385$ ) of notified cases. In comparison, the former Hunter Area Health Service had 4% ( $n = 78$ ) of notifications in the 0–4-year age group. An explanation for this difference is the location of Broken Hill city, which is in the immediate vicinity of the active mine site with above ground historical waste disposal, and regional soils that have natural lead deposits. These sources produce ongoing exposure from lead-laden dust in and around houses where children play.<sup>19</sup>

Occupational exposures are also likely to account for the differences in notification rates between men and women which became more evident from the age of 15 years. In the former Hunter Area Health Service, lead poisoning notifications reduced following the closure of the Lake Macquarie smelter in 2003.<sup>20</sup> Increased lead mining activity in the former Macquarie Area Health Service (Cobar) since 2003<sup>21</sup> has resulted in miners being the most frequently notified occupation. Other occupations and hobbies that have been associated with lead exposures include battery making and recycling, soldering, stained glass manufacture and lead-based paint abatement.<sup>3,22</sup>

Since 1991 the blood lead screening of children in Broken Hill has underpinned education and risk reduction interventions provided to individuals and their families.<sup>23,24</sup> These interventions resulted in almost 75% of children aged 1–4 years recording blood lead levels below 10 µg/dL by 2007.<sup>25</sup> In the north Lake Macquarie area, the positive influence of public health action allowed active surveillance to stop after mean blood lead levels in children decreased to less than 5 µg/dL in 2006,<sup>18</sup> 3 years after the closure of the smelter.

From December 2011, the notifiable blood lead level in NSW has been reduced to 10 µg/dL in line with the current National Health and Medical Research Council recommendation.<sup>3</sup> A review conducted by the Centers for Disease Control and Prevention in the United States concluded that there is sufficient evidence for adverse health effects in children and adults at blood lead concentrations below 5 µg/dL.<sup>26</sup> Both of these recommendations

have implications for public health policy and practice in NSW.

## Conclusion

Active surveillance practices for lead poisoning in NSW have enhanced our knowledge of this condition, particularly in the former Hunter and Far West Area Health Services. Encouragingly, a large reduction in notifications and the concentrations of blood lead samples was observed from 1998 to 2008. Despite these reductions, there remains an over-representation of children and miners in more recent years of analysis. Importantly, these findings support ongoing primary prevention, improved surveillance measures and the mandatory notification of lead poisoning, which remain essential to addressing lead poisoning in NSW.

\*The *Public Health Act 2010* (NSW) (<http://www.health.nsw.gov.au/phact/>)

The *Public Health Act 2010* (NSW) was passed by the NSW Parliament in December 2010 and commenced on 1 September 2012. The *Public Health Regulation 2012* was approved in July 2012 and commenced, along with the *Public Health Act 2010* (NSW), on 1 September 2012. The objectives of the Regulation are to support the smooth operation of the Act. The Act carries over many of the provisions of the *Public Health Act 1991* (NSW) while also including a range of new provisions.
