## Additional explanation of field methods

Field plots were selected using the following criteria: 1) vegetation composed entirely of chaparral (no portion of the area classified as coastal sage scrub or coast live oak) and 2) reasonably accessible (within 100 m of a road or trail). Plot boundaries were surveyed in the field using a Trimble GeoXM handheld Global Positioning System (GPS) unit with a post-processed accuracy of 1 to 3 m . Within each plot we measured with digital calipers the diameter of all stems 0.4 cm or greater in diameter at 10 cm above the ground, and recorded the species and whether stems were live, dead, or charred.

The biomass of each plot at the year of field sampling was calculated using species-specific regression equations relating stem basal area to dry biomass. We calculated coefficients for the relationship of dry above-ground biomass $(A G B)$ as a power function of basal area $(B A)$ with a bias correction applied (Baskerville 1972; Sprugel 1983):

$$
\begin{equation*}
A G B=B_{0}(B A)^{B_{1}} \mathbf{e}^{0.5 s} \tag{1}
\end{equation*}
$$

where $s$ is the residual mean square, $B_{0}$ is the proportionality coefficient, and $B_{1}$ is the scaling exponent.

We generated species-specific equations for Adenostoma fasciculatum, Ceanothus crassifolius, Ceanothus oliganthus, Eriodictyon trichocalyx, and Quercus berberidifolia. We combined the measurements from each species sampled in more than one year to create a single regression equation for each species. We also used the regression equation for Salvia mellifera developed by Riggan and others (1988), and a regression equation calculated using all pooled stem measurements to calculate the biomass of other species that were uncommon in the field plots. Regression models were run separately for live and dead stems. Charred stems were only occasionally found in the plots, and were not the main focus of the study, so charred biomass was roughly estimated in these areas using half the value given by the appropriate equation for dead biomass.

One shrub per species per day was selected to serve as a representative sample to estimate the dry weight of freshly cut biomass. The sampled shrub was brought to the lab where it was separated into small ( $<0.5 \mathrm{~cm}$ ), medium ( 0.5 cm to 2 cm ) and large ( $>2 \mathrm{~cm}$ ) diameter fractions. Each size fraction was weighed and subsampled to determine water content. Shrub components were dried to a constant mass in a drying oven at $100^{\circ} \mathrm{C}$. The total shrub water content was determined by applying the water content value measured for each size fraction to the total biomass of each corresponding size fraction. This value was then applied to all shrubs of that species sampled on that day.

A species-specific equation was used to calculate shrub biomass for an average of $88 \%$ (and a per-plot range of $43-100 \%$ ) of the total basal area present in each plot. The stems measured in the study plots were occasionally larger than the stems sampled destructively to calculate regression equations. Across all plots, an average of $2 \%$ of stems (and a per-plot range of $0-14 \%$ ) were so large as to require an extrapolation of the regression equation to estimate biomass.

Table S3. Biomass of total live shrub biomass (includes dead stems attached to otherwise live shrubs), entirely dead shrubs, charred stems, and totals per species

The percent of dead stem biomass relative to total biomass is presented for each species total. Plots listed in italics had insufficient stem cross section samples and were not included in biomass per year estimations. Species listed include Ceanothus crassifolius (Cc), Adenostoma fasciculatum (Af), Salvia mellifera (Sm),
Ceanothus oliganthus (Co), Eriodictyon trichocalyx (Et), Quercus berberidifolia (Qb), Eriogonum fasciculatum (Ef), Cercocarpus betuloides (Cb), Heteromeles arbutifolia (Ha), Prunus ilicifolia (Pi)
